PHYSIOLOGICAL RESPONSES AT VARIOUS LACTATE MARKERS FOR RUNNING AT 4 AND 8 MINUTE TREADMILL INCREMENTS

James Peter Gavin, Stephen Daniel Myers, Marc Elizabeth Theodorus Willems
Department of Sport and Exercise Sciences, University of Chichester, Chichester, United Kingdom

Abstract
We compared physiological responses corresponding to speeds at plasma lactate markers between incremental treadmill running of 4 and 8 min stages in fifteen healthy men (23 ± 4 yrs, 1.78 ± 0.49 m, 72.7 ± 10.8 kg). Treadmill speed, oxygen uptake (\(\dot{V}O_2\)), heart rate (HR), rating of perceived exertion (RPE) and plasma lactate were measured for each stage, and calculated at: fixed blood lactate accumulation (FBLA) 4.0 mmol/L, an initial 1 mmol/L rise, deviation maximum (\(D_m\)), lactate threshold (LT) and log-log LT. There was no effect (p>0.05) of stage duration on speed, \(\dot{V}O_2\), HR and RPE at fixed markers. For 8 min stages, speed was lower at modelled markers: \(D_m\) (-1.1 km/h; p=0.001), LT (-0.9 km/h; p=0.008) and log-log LT (-0.8 km/h; p=0.006), yet RPE was higher and \(\dot{V}O_2\) lower for LT (1.1, p=0.02; -0.27 L/min, p=0.01) and log-log LT (1.4, p=0.03; -0.29 L/min, p=0.002). Lactate and \(\dot{V}O_2\) were greater at 8 km/h for 4 min (p=0.0001), then similar until 11 km/h, with a trend towards elevated plasma lactate for 4 min thereafter. When applying lactate threshold markers to assess physiological responses to incremental running, protocols using prolonged stage durations may underestimate marker running speed.

Key words: Incremental exercise, Lactate markers, Oxygen uptake, Stage duration, Threshold.

INTRODUCTION
Incremental exercise with measurement of physiological responses, coupled with blood lactate sampling, is used to predict endurance performance (Coyle, 1999; Roecker, Schotte, Niess, Horstmann & Dickhuth, 1998) prescribe exercise intensity and monitor adaptation (Bentley, Newell & Bishop, 2007). Aerobic capacity and the anaerobic threshold (AT) can be assessed in this manner during sub-maximal tests (Davis, 1985; Wasserman, Whipp, Koyl & Beaver, 1973) in both athletic (Coen, Urhausen & Kindermann, 2001) and clinical populations (Katz, Berkowitz & Lejemtel, 1992). Running speed eliciting AT has greater association with endurance performance in comparison to other predictive indices such as running economy, maximal oxygen uptake (\(\dot{V}O_2\max\)) and muscle fibre composition (Farrell, Wilmore, Coyle, Billing & Costill, 1979; Sjodin & Jacobs, 1981). To better describe the workload -response relationship, fixed and modelled lactate markers can be calculated from blood samples collected at each increment. Lundberg et al (1986) established the LT via a computational method, whereby the lactate-workload response was modelled with two phase linear regression. Advancing upon this, Beaver and colleagues (1985) suggested applying a log transform to both lactate and workload values. Alternatively, fixed blood lactate accumulations (FBLA), such as 2.0 and 4.0 mmol/L (Heck et al., 1985; Kindermann, Simon & Keul, 1979) and the initial 1 mmol/L rise from baseline, rely upon blood lactate concentration responding in a monotonous, curvilinear fashion to workload increments. Fixed markers allow ease of use, yet ignore individual lactate variability at rest and during exercise. Considering individual variation, the deviation maximum (\(D_m\)) detects workload yielding the maximum perpendicular from a line connecting the first and the final lactate-workload points to the estimated polynomial (Cheng et al., 1992). The calculation of the workload corresponding to the \(D_m\) is therefore dependent on the individual’s resting blood lactate concentration.

Lactate kinetics are sensitive to exercise incrementation rate and duration, both of which may be manipulated according to sporting performance demands and the individual (Stockhausen, Grathwohl, Burkin, Spranz & Keul, 1997). Typically stage increments between 3 and 6 min duration are used, based upon the attainment of lactate and oxygen uptake (\(\dot{V}O_2\)) steady-states (Bentley, Newell & Bishop, 2007). Previous research has found shorter stage durations to result in overestimation of the AT (Coen, Urhausen & Kindermann, 2001; Whipp, Davis, Torres & Wasserman, 1981), in addition to increasing workload at the LT (Bentley, McNaughton & Batterham, 2001). The latter reported 3 min stage increments had the effect of elevating power output at LT, in comparison to 8 min stages for cycling exercise. Yet, no effect was seen for workload, \(\dot{V}O_2\) and heart rate (HR) at the FBLA 4.0 mmol/L. Step durations
less than 3 min are unlikely to satisfy steady-state, and thus physiological response corresponding to particular lactate markers. Prolonged stages, in contrast, may allow lactate equilibrium, yet compromise peak $\dot{V}_{\text{O}_2}$ attainment and promote premature fatigue. Differing muscular recruitment patterns (Beneke & von Duvillard, 1996) and maximal lactate steady-state responses (Beneke, Leithauser & Hutler, 2001) make direct comparisons between running and cycling difficult. For running, stages beyond 6 min have been recommended with the FBLA 4.0 mmol/L to avoid delay in blood lactate response (Foxdal, Sjödin & Sjödin, 1996). To expand upon findings of Bentley’s (2001) and Foxdal’s (1996) groups, our aim was to examine physiological responses corresponding to speeds at lactate markers using incremental treadmill running of traditional, 4 min, and prolonged, 8 min stage durations.

**MATERIALS AND METHODS**

**Participants**
Fifteen healthy men (mean ± SD; age 23 ± 4 yrs, height 1.78 ± 0.49 m, body mass 72.7 ± 10.8 kg) volunteered and provided written informed consent for participation in the study. Volunteers completed a medical and an International Physical Activity Questionnaire (IPAQ), conforming to high levels of habitual physical activity (2877.5 ± 1304.4 MET-min/wk) (Bauman et al., 2009). Ethical approval for the research protocol was approved of by the University of Chichester Ethics Committee and conducted in accordance with the Helsinki Declaration.

**Procedures**
Participants visited the same temperature controlled laboratory (19 – 22°C) on five occasions to perform: a familiarisation, and repeated incremental running trials of 4 and 8 min stages in a randomised order within a four wk period (Figure 1). All were instructed to refrain from strenuous exercise 24 h prior to each visit and a minimum of 48 h was allocated between sessions. Volunteers reported to the laboratory euhydrated, having not eaten, or consumed caffeine 3 h prior. Participants ran at a 1% gradient with an incrementation rate of 1 km/h every 4 or 8 min on a Woodway Ergo ELG 70 powered treadmill (Weil am Rhein, Germany). Subsequently, lactate-speed data was plotted using lactate analysis software (Newell et al., 2007) with treadmill speed, $\dot{V}_{\text{O}_2}$, HR and rating of perceived exertion (RPE) calculated corresponding to the markers: FBLA 4.0 mmol/L, an initial 1 mmol/L rise, $D_{\text{max}}$, LT and log-log LT.

Trials began with explanation of experimental protocol, then height was measured with a free-standing stadiometer (Holtain Ltd., Crymych, UK) and body mass using digital health scales (Seca Ltd., Birmingham, UK). All were familiarised with Borg’s scale (Borg, Hassmen & Lagerstrom, 1987) for RPE and positioned with a heart rate monitor (Polar Electro Oy, Kempele, Finland). At rest, heart rate and plasma lactate were recorded in the final 30 s of a 5 min, seated period. Next participants warmed up at 8 km/h for 5 min on the treadmill. Following a brief interval, exercise commenced with participants lowering themselves onto the treadmill belt when the start speed of 8 km/h was attained. Volunteers performed between four and ten stages with an incrementation rate of 1 km/h every 4 or 8 min. Participants were asked for RPE in the final 30 s of each stage, before straddling the treadmill upon stage completion during which a finger-tip capillary blood sample was collected.

**Measurement Procedures**
Respiratory gases were monitored breath-by-breath, concurrent with HR, using a portable metabolic cart (Cosmed K4b², Rome, Italy). Prior to each trial, the system was calibrated according to manufacturer’s recommendations (Cosmed K4b² User Manual). For analysis, $\dot{V}_{\text{O}_2}$ and HR were recorded as 30 s averages, and then reported during the final 30 s of each stage with treadmill speed, RPE and blood lactate concentration (Figure 1).

Plasma lactate was analysed via a ~25 µl finger prick blood sample collected from the right index finger from an incision made using a Haemolance plus high flow lancet (Haemedic AB, Munka Ljungby, Sweden). At rest and on stage completion, fingertip capillary blood samples were drawn into non-lysed, EDTA-treated microvets (Sarstedt Aktiengesellschaft & Co., Nürnberg, Germany) and analysed in duplicate for plasma lactate (2300 STAT Plus™, YSI Life Sciences, Yellow Springs, USA). Where lactate concentrations varied less than 0.4 mmol/L between samples, the mean was reported. Where lactate concentration varied greater than 0.4 mmol/L, a third analysis was conducted with the mean of the two closest samples recorded (Grant et al., 2002). Lactate analysis software (Newell et al., 2007) was used to establish treadmill speed, $\dot{V}_{\text{O}_2}$, HR and RPE at the lactate markers: FBLA 4.0 mmol/L, the initial 1 mmol/L rise, $D_{\text{max}}$, LT and log-log LT.
Statistical Analysis
Physiological responses between 4 and 8 min stages were analysed by a Student’s t-test for paired samples. One-way repeated measures analyses of variance (ANOVA) with pairwise comparisons were used to assess mean lactate

and $\dot{V}O_2$ for: 4 min, 4 min at 8 min, and 8 min stages. Statistical analyses were calculated using PASW Statistics 18.0 for Windows (California, USA) with statistical significance set to a Type I error level of $p<0.05$.

RESULTS
Mean maximal running speed was faster during 4 min (14.4 ± 1.4 km/h; $p=0.001$), in comparison to 8 min trials (12.6 ± 1.3 km/h) (Table 1). There was no effect of duration on speed, $\dot{V}O_2$, HR and RPE at fixed markers: FBLA 4.0 mmol/L and the initial 1 mmol/L rise. Speed, $\dot{V}O_2$ and HR were similar; yet RPE appeared elevated for 4 min at the FBLA 4.0 mmol/L (0.7; $p=0.46$) and the initial 1 mmol/L rise (0.9; $p=0.38$), in comparison to 8 min. For 8 min, speed was lower at modelled markers: $D_{max}$ (-1.1 km/h; $p=0.01$) and log-log LT (1.4, $p=0.03$; -0.29 L/min, $p=0.002$) for 8 min trials. This was not observed for $D_{max}$ ($p=0.11$).

Following stage one (8 km/h), plasma lactate concentration was 0.2 mmol/L lower for 8 min than 4 min ($p=0.008$), and 4 min at 8 min ($p=0.03$) respectively. Thereafter, plasma lactate was similar until the end of stage four (11 km/h) ($p=0.05$). For subsequent speeds (12 to 15 km/h), there was a trend towards higher lactate concentrations during 4 min stages, than 8 min (Table 2). For example, at 12 km/h lactate was 3.5 mmol/L for 4 min and 2.8 mmol/L for 8 min. At 13 km/h lactate was 4.5 mmol/L for 4 min and 3.0 mmol/L for 8 min, respectively.

* Significant difference from 4 min values, p<0.05. † Significant difference from 4 min at 8 min values, p<0.01. n = participant number.
Mean $\dot{V}O_2$ was elevated during 4 min (2.91 L/min), in comparison to 8 min trials (2.57 L/min; $p=0.0001$), following the first stage, 8 km/h until 11 km/h (Figure 2). At 4 min during 8 min, mean $\dot{V}O_2$ was also reduced when compared to that measured at the stage end, at 8 min (2.48 L/min; $p=0.0002$). At 9 km/h during 4 min stages, $\dot{V}O_2$ (3.17 L/min) remained above both, 4 min at 8 min (2.86 L/min; $p=0.0001$) and 8 min (2.89 L/min; $p=0.001$). At 10 and 11 km/h, $\dot{V}O_2$ was similar between stage lengths, and no difference was observed above 11 km/h. This may be attributable to fewer participants completing stage increments above this speed, resulting in insufficient paired data sets for statistical analysis. In accordance to our plasma lactate data, for 12 km/h $\dot{V}O_2$ sampled was not different between 4 (3.61 L/min) and 8 min stages (3.4 L/min) ($p=0.13$). Dissimilar to our plasma lactate response, at 13, 14 and 15 km/h, $\dot{V}O_2$ for 8 min appeared to rise steeply, $\dot{V}O_2$ showing a trend of surpassing that of 4 min trials at 14 and 15 km/h. Therefore, the effect of stage duration on $\dot{V}O_2$ response was not reflected by plasma lactate response at running speeds above 12 km/h.

**FIGURE 2.** Oxygen uptake ($\dot{V}O_2$) (L/min) measured at the completion of each running speed (km/h) during incremental running trials of 4 and 8 min stage durations, as well as for 4 min during 8 min (mean ± SD). * Significant difference from 4 min values, $p<0.05$.

**DISCUSSION**
The incrementation rate and stage duration of incremental exercise protocols are adapted according to activity-specific demands and the characteristics of the population under assessment. The purpose of the present study was to compare physiological responses ($\dot{V}O_2$, HR and RPE) corresponding to speeds at plasma lactate markers during repeat, incremental treadmill running trials of 4 and 8 min stage durations in young men. These findings suggest that trials using stage durations of 8 min have the effect of reducing the running speed, but increasing the perception of exercise intensity at the LT and log-log LT. Furthermore, there was no effect of stage duration on selected physiological responses when using the fixed plasma lactate markers: FBLA 4.0 mmol/L and the initial 1 mmol/L rise, in our cohort.

Production and elimination of intramuscular lactate determines circulating blood lactate concentration (MacRae, Dennis, Bosch & Noakes, 1992), and as such, blood lactate responds in a steady-state manner at low- and moderate-running speeds sub LT. At speeds above the LT, blood lactate accumulation will occur, unabating even when the intensity is reduced to constant speed. Blood lactate response will only decrease when running speed is reduced to those intensities below the LT. The duration an individual is exposed to a workload during incremental exercise remains controversial. Previously, Yoshida and co-workers (1984) observed no difference in $\dot{V}O_2$.
at the initial rise above baseline and FBLA 4.0 mmol/L during incremental cycling protocols of 1 and 4 min stages. However, workloads at the respective markers were greater for the shorter, 1 min stages. It has been proposed that stage increments of at least 3 min are adequate to reach lactate steady-state; stages of longer duration allow lactate diffusion to reach an equilibrium-state between muscle and blood, thus permitting greater sensitivity for blood lactate sampling (Billat, Sirvent, Py, Koralsztein & Mercier, 2003). The reliability of 3 min increments to identify fixed blood lactate markers and the LT was tested by Weltman and colleagues (1990) in a cohort of male runners. Assessed against a discontinuous, criterion protocol of 10 min stages; the 3 min protocol elicited similar running speeds at the FBLAs: 2.0, 2.5 and 4.0 mmol/L and the LT, as well as \( \dot{V}O_2 \), suggesting high reliability. For repeat trials of 3 min increments, mean running speed and \( \dot{V}O_2 \) were 16.2 km/h and 4.13 L/min at FBLA 4.0 mmol/L; and 13.0 km/h and 3.28 L/min at the LT, respectively. Dissimilarities in our data (12.9 km/h and 3.78 L/min at FBLA 4.0 mmol/L; 11.4 km/h and 3.51 L/min at the LT) may be due to differences in the training status of populations sampled. Weltman et al (1990) recruited male runners accumulating a minimum of 40 km per wk; whereas we used recreationally active, male students who did not all undertake regular running. Following endurance training, higher running speeds can be attained at a specific lactate marker leading to a rightward shift in the lactate-speed relationship. If this does not sufficiently explain the disparities in our findings, marker suitability for stage duration may.

Similarly to Weltman (1990) stage duration had no effect on running speed at FBLA 4.0 mmol/L; yet for 4 min stages we observed faster speed concomitant with elevated \( \dot{V}O_2 \) at LT. Being regular runners, it is plausible that their cohort had a superior lactate buffering capacity, allowing them to tolerate the 10 min criterion protocol to a greater extent than ours during the 8 min protocol. Thus, reaching metabolic breakpoint at similar running speeds to shorter stage durations, which may explain the attainment of LT at slower running speeds during 8 min stages in our investigation. Interestingly, workload at D_{max} was elevated for 4 min, in comparison to 8 min trials, without influence upon \( \dot{V}O_2 \), HR and RPE. Previously, we have found poor reproducibility for the D_{max} during repeated, 4 and 8 min stage protocols (Gavin, Myers & Willems, unpublished results). D_{max} identifies threshold speed corresponding to the maximal perpendicular of a line connecting the first and the final lactate concentrations from a third-degree polynomial lactate-speed curve; thus dependent upon the curve expressing a smooth, parabolic function (Figure 3). As can be seen in Figure 4, this marker is unsuitable with the occurrence of a breakpoint, and relies upon the individual exerting maximal effort throughout the trial. As little consensus exists to an established fitting procedure, it appears apt to consider the incremental protocol design when selecting lactate markers to determine exercise intensity and monitor adaptation. Furthermore, the practice of applying a single marker for analysis of lactate-workload relationships should be discouraged.

**FIGURE 3.** Plasma lactate-speed relationship for a single participant analysed from a 4 min stage incremental treadmill running trial with selected lactate markers (FBLA 4.0 mmol/L = 11.1 km/h; initial 1 mmol/L rise = 9.2 km/h; D_{max} = 9.9 km/h).
Previous studies have observed elevated lactate response during shorter stage protocols, when compared against longer stage increments (Bentley, McNaughton & Batterham, 2001; Kuipers, Rietjens, Verstappen, Schoenmakers & Hofman, 2003). To our knowledge, only one investigation has compared difference in blood lactate response to incremental running exercise of 4 and 8 min stages (Foxdal, Sjodin & Sjodin, 1996). These authors found 4 and 6 min stages insufficient to achieve lactate steady-state in a group of firemen and marathon runners. Furthermore, the greater relationship between blood lactate sampled from incremental and constant-speed exercise observed in the running cohort is indicative of a training-induced regulatory effect likely to influence the use of FBLA 4.0 mmol/L for training prescription. Here, faster running speed at the FBLA 4.0 mmol/L was noted for 4 min, when compared to 8 min stages. In contrast, we found no effect of stage duration on speed at FBLA 4.0 mmol/L; we used non-lysed, plasma capillary samples, whereas Foxdal’s group (1996) used haemolysed capillary blood for analysis. Although capillary samples are known to reflect arterial lactate values, the disparity may be attributable to the non-homogenous distribution of lactate in blood. Blood sampling and analysis media vary throughout the literature, making direct comparison of data difficult. Whole venous samples have been reported to produce lower concentrations than fingertip samples during 4 min stage incremental treadmill running (El-Sayed, George & Dyson, 1993). Analytically, samples from plasma tend to be higher than those of whole- and haemolysed blood (Williams, Armstrong & Kirby, 1992); this is due to the erythrocyte membrane acting as a barrier to lactate transit between plasma and red blood cells with changing lactate concentration. Various have cited difference in workload at fixed lactate markers (Bishop, Smith, Kime, Mayo & Tin, 1992; Foxdal, Sjodin, Ostman & Sjodin, 1991; Williams, Armstrong & Kirby, 1992), but not the LT (Robergs et al., 1990; Yoshida, 1984) when collecting from venous or capillary, and analysing via plasma or haemolysed blood.

A secondary, but important finding of this study was the possible dissociation of plasma lactate concentration and $\dot{V}_{O_2}$ for faster running speeds during 4 min stage trials. There appeared an increased blood lactate response from stages five to seven (12 to 15 km/h) during 4 min stages, with the difference increasing with advancing stages (stage eight, mean plasma lactate concentrations: 6.3 mmol/L (4 min); 4.5 mmol/L (8 min)). This was reflected by an observation of higher $\dot{V}_{O_2}$ from stages one to six (8 to 13 km/h) during 4 min stages, yet by stages six and seven (14 and 15 km/h) $\dot{V}_{O_2}$ during 8 min had exceeded that of 4 min. Mean maximal treadmill running speed achieved during 4 min trials was greater than that of 8 min trials, with the length of all 8 min trials in
excess of 4 min trials. The contrasting natures of
the two protocols impose specific physiological
demands upon the individual, therefore
influencing the particular selection of lactate
markers and the subsequent prescription of
training intensities. When comparing power
output, HR and \( \dot{V}_O_2 \) between 3 and 8 min stage
protocols for incremental cycling, Bentley et al
(2001) reported 3 min increments may be
adequate when using the FBLA 4.0 mmol/L, but
not the LT. Prolonged stages had the effect of
increasing power output at the LT, which may
explain the possible \( \dot{V}_O_2 \), slow component
observed for our 8 min trials. Lactate has been
implicated as a causative factor leading to the
\( \dot{V}_O_2 \) slow component and muscle fatigue
(Zoladz, Gladden, Hogan, Nieckarz & Grassi,
2008). Steady-state \( \dot{V}_O_2 \) occurs during low-
to moderate-intensity exercise, however with
transition to high-intensity exercise beyond the
LT, \( \dot{V}_O_2 \) rises continuously until the cessation of
exercise (Whipp & Wasserman, 1972). Once the
LT has been surpassed during incremental
running exercise, the \( \dot{V}_O_2 \)-speed relationship
exhibits a non-proportional, curvilinear response
indicative of muscular fatigue. In this manner,
fixed plasma lactate markers may overestimate
HR and \( \dot{V}_O_2 \) when using stages of prolonged
duration as such markers are unable to discern
individual metabolic differences, and may lack
sensitivity to distinguish influence of muscular
fatigue.

Practical Applications

This investigation compared the treadmill speed,
\( \dot{V}_O_2 \), HR, and RPE at fixed and modelled plasma
lactate markers from data recorded during
repeat incremental running trials of 4 and 8 min
stages in healthy men. This report provides the
following suggestions for sport and exercise
scientists when measuring physiological
responses to prescribe exercise intensity and/or
monitoring training status:

- 8 min stage incremental tests may
  compromise maximal running speed due to
  increased effort perception and onset of
  muscular fatigue. This, in turn, will
  underestimate running speed when using
  various blood lactate markers.

- The practitioner should consider the effect
  that prolonged stages may have on the
  blood lactate response, and particularly the
  calculation of lactate endurance markers.
  For example, the \( D_{max} \) uses the first and final
  lactate concentrations to determine
  speed/workload. If prolonged stages do not
  increase lactate concentration sufficiently by
  test termination, relatively lower
  speed/workload will be calculated.

- Incremental exercise protocols should be
designed according to the training status
and conditioning of the athlete, as well their
sport-specific demands. For those not
endurance trained, longer stages may
prematurely fatigue without imposing
sufficient cardiorespiratory stress.
